Supporting Information

ABSTRACT: In this work, we developed a novel strategy using fluorescent quantum dots (QDs) combined with molecularly imprinted polymers (MIPs) on three-dimensional (3D) origami paper-based microfluidic devices for specific recognition and sensitive detection of phycocyanin. This method can realize the liquid phase of QDs@MIPs being transferred to the solid-phase paper base and achieve easy portability for the analysis. Under optimal conditions, we successfully demonstrated the proposed paper@QDs@MIPs 3D microfluidic chip for the sensitive and selective detection of phycocyanin protein target in a simple and robust manner. Our results revealed that the method exhibited a dynamic response to phycocyanin in the range of 10–50 mg/L with a limit of detection of 2 mg/L. Importantly, this device could provide quantitative information very conveniently and show great potential to be further extended to the detection of other proteins or biomarkers for environmental and food safety research.

KEYWORDS: paper-based microfluidic devices, molecularly imprinted polymers (MIPs), quantum dot, phycocyanin, fluorescence

Phycocyanin, a blue-colored photosynthetic accessory pigment protein, is widely distributed in seawater, lake water, and algae microbes in drinking water, and has good survival ability. In addition, phycocyanin is a new desirable fluorescent marker with high stability and sensitivity and could be applied in biomedical and environmental fields. In the case of eutrophication of the water environment it often leads to algae bloom, causing serious deterioration of water quality.^{1–3} The content of toxic substances produced by blue-green algae, including β -methylamino-alanine,⁴ algal toxins,⁵ nodularin,⁶ and saxitoxin,^{2,7,8} in the water is also increased and represents a serious threat to the safety of marine life and humans. Therefore, to protect the ecological balance of the environment, it is necessary to monitor and control the quantity of cyanobacteria. As its concentration can effectively represent cyanobacterial biomass, it can be used as an index of

cyanobacteria outbreak and plays an important role in monitoring the marine ecological environment.⁹ Current methods of detecting phycocyanin concentration mainly involve remote sensing methods,^{10,11} UV, and fluorescence detection.^{12,13} In addition, direct analysis of the water content of phycocyanin often requires separation and purification steps. Moreover, high cost and time-consuming methods add to the challenge, and development of a low-cost, fast, and efficient method for the detection of phycocyanin is urgently needed.

Since the concept of microfluidic paper-based analytical devices (μ PADs) was first proposed by the Whitesides group,¹⁴ versatile μ PADs have recently attracted increasing atten-

tion.^{15,16} This approach combines several great advantages such as miniaturization, automation, and integration. Moreover, compared with traditional materials such as PDMS and glass, it could present superior features such as low cost, ease of use, and facile portability, and operation. Hence, a large number of techniques including colorimetric,¹⁷ electrochemical,^{18–20} chemiluminescence,²¹ surface enhanced Raman spectroscopy (SERS) sensors,^{22–24} and biochemical analyses^{25–27} have been reported, mainly focusing on point-of-care (POC),^{28–31} biochemical tests,^{32,33} and environmental monitoring.^{34,35}

Molecularly imprinted polymer (MIP) technologies concern creation of tailor-made binding sites in a polymer matrix with memory of the shape, size, and functional groups of the template molecules, and provide unique advantages such as excellent recognition specificity, high selectivity, and good reusability.^{36,37}

Therefore, the combination of the MIP technique with paper-based microfluidics provides potential reproducible results for the quantitative measurement of analytes. Recently some emerging techniques have used molecularly imprinted polymers and quantum dots (QDs) techniques on a paper-based platform. Noor and Krull developed a fluorescence resonance energy transfer system by immobilizing multicolor QDs as donors.³⁸ Our group proposed SiO₂@QDs@ms-MIPs and magnetic micromotor-driven sensor strategies for detection of phycocyanin.^{12,39} Yu's group presented a paper-based MIP-grafted multidisk plate for chemiluminescence detection through an indirect competitive assay⁴⁰ and developed a photoelectrochemical sensor by immobilizing QDs@MIPs on screen-printed working electrodes.⁴¹ However, there is still a lack of strategies for grafting MIPs and quantum dots directly on the paper to realize simple and facile detection.

To address these issues, we presented a new kind of quantum dot wrapped with molecularly imprinted polymers on 3D origami paper-based microfluidic chip devices that allow direct monitoring of phycocyanin. To the best of our knowledge, the quantum dot was first grafted on the paper through synthesizing the paper@QDs@PC-MIPs component and realizing the liquid phase of QDs@MIPs being transferred to the solid phase paper base. The paper@QDs@PC-MIPs component could be easily assembled into the 3D origami paper-based devices, and it provides a simple, portable, and user-friendly way for phycocyanin detection with desirable results.

EXPERIMENTAL SECTION

Materials. Phycocyanin (PC) powder was supplied by Shandong Oriental Ocean Company (Yantai, China). Sodium borohydride, cadmium chloride, *N*-hydroxysuccinimide (NHS), and 1-ethyl-3-(dimethylamino)propyl carbodiimide hydrochloride (EDC) were purchased from Aladdin Industrial Corporation (Shanghai, China). Albumin from chicken egg, bovine serum albumin (BSA), and 3-aminopropyl triethoxysilane (APTES) were obtained from Sigma-Aldrich Corporation (Shanghai, China). Hemoglobin from bovine blood (BHB) was purchased from Solarbio. Thioglycolic acid (TGA), ethanol, phosphate buffered saline (PBS), and other chemical reagents were of at least analytical grade and were purchased from Sinopharm Chemical Reagent (Shanghai, China). Whatman No. 1 filter paper was purchased from GE (Shanghai, China). All aqueous solutions used throughout the work were prepared with ultrapure water (18.2 MΩ), which was produced by a Pall Cascade laboratory water system (Millipore, Bedford, MA, USA).

Synthesis of Water-Soluble CdTe QDs. Water-soluble TGA-modified CdTe QDs were synthesized according to the reported method.⁴² To form the cadmium precursor, 68.4 mg of 2CdCl₂·5H₂O,

63 μL of TGA, and 75 mL of highly purified water were mixed in a three-necked flask. The mixture was adjusted to pH 9–9.2 with 1.0 M NaOH and stirred under N₂ for 20 min. Meanwhile, 38.3 mg tellurium powder, 40.0 mg NaBH₄, 1.5 mL ethanol, and 0.5 mL highly purified water were mixed in a sealed 2 mL tube. The solution was heated at 40 °C for 4 h to format NaHTe solution and then 1 mL of freshly prepared NaHTe aqueous solution was injected into the reaction system under stirring. The solution was heated until boiling and refluxed for 2 h. The resultant TGA-capped CdTe QDs exhibited strong yellow-green fluorescence at 545–560 nm. CdTe Quantum dot solution was stored in the dark and its fluorescence intensity did not change significantly over 60 days.

Synthesis of Fluorescent Sensors Filter Paper Substrate (Paper@QDs). The filter paper substrate was cut to a size of 8 mm × 8 mm, dipped in 0.2 mol/L HCl solution for 30 min, and washed three times with ultrapure water to remove excess HCl. The paper was immersed in 20 mL of ethanol/water (50%) and 200 μL of APTES was added for 2–4 h for addition of receiving amino groups. After removal of excess alcohol by DDI water, the paper substrate was retained and set aside. A total of 10 mL CdTe quantum dots was slowly added dropwise to the filter paper substrate, and then 6 mL of 20 mg/mL EDC (1-ethyl-3-(3-(dimethylamino)propyl) carbodiimide) and 6 mL of 10 mg/mL NHS (*N*-hydroxysuccinimide) solution were added and reacted by oscillation at room temperature in the dark for 8 h to allow grafting of the quantum dots at the surface of the paper substrate (shown in Figure 3). Finally, the product was rinsed 3–5 times in 0.01 mol/L phosphate buffer solution (pH = 7.5) and ultrapure water.

Synthesis of Paper@QDs@PC-MIPs (PQP-MIPs) Structure. The PQP-MIPs were prepared by a surface imprinting process similar to reported procedures with some modifications.⁴³ To form the complex, 5 mg phycocyanin and 40 μL APTES were added to 20 mL highly purified water, followed by addition of 50 μL TEOS as cross-linker and 50 μL ammonia oscillation at 80–100 rpm/min in a rotary shaker for 30 min to allow polymerization. The prepared paper@QDs was incubated in the polymerization solution in the dark for 12 h to graft the phycocyanin-MIPs. The resultant PQP-MIPs was rinsed three times to remove residues. A 1% Triton X-100 solution was used as the eluent to remove excess phycocyanin from the PC-MIPs. For comparison, nonimprinted polymers paper@QDs@NIPs (hereafter called NIPs for simplicity) were prepared as a control using the same procedure and conditions, but in the absence of phycocyanin. In this work, the paper@QDs have a covalent bond that makes the quantum dots graft on the paper firmly, and holds the signal stable. To prove this, the fluorescence intensity investigations of QDs on paper (covalently immobilized or physically adsorbed) before and after rinsing were carried out (as shown in Figure S1). It can be observed that the fluorescence intensity was very weak for the QDs only depending on the physical adsorption (curve c) compared with the covalently immobilized QDs (curve a) on the paper. In addition, after the rinsing, the fluorescence intensity of covalently immobilized QDs did not change significantly (curve b) and it indicated that the covalent bond made the quantum dots graft on the paper firmly, and maintained the signal high and stable.

Instruments. The chip was designed with drawing software (Adobe Illustrator) and then directly printed onto the filter paper (Whatman chromatography No. 1 paper, GE) by a wax printer (XEROX Phaser 8560DN) with maximum resolution of 2400 dpi. After printing, the paper was kept in an oven at 150 °C for 20 s to let the wax penetrate through the paper completely, forming a hydrophobic barrier as described in previous reports.^{18,22}

Modifications of the paper were imaged by scanning electron microscopy (SEM; JSM 5600 LV, operating at 20 kV). Fluorescence spectra were obtained using a spectrofluorometer (Fluoromax-4, HORIBA): excitation light was set at 396 nm and the emission spectra were recorded from 500–650 nm for QDs. A fluorescence microscope (IX51, Olympus) equipped with a CCD camera was used to observe the fluorescence microscopy image on a glass slide. Infrared spectra were obtained from Fourier transform infrared spectrometer (Nicolet iS10, Thermo Scientific) to examine the preparation process. UV/vis

absorption spectra were recorded on a spectrophotometer (Nano-Drop2000/2000C, Thermo Scientific) to test the binding properties of polymers.

RESULTS AND DISCUSSIONS

Fabrication and Characterization of Paper@QDs@PC-MIPs Base Component. Figure 1 schematically illustrates the

Figure 1. (a) Photograph of the paper@QDs@PC-MIPs μ PADs. (b) Schematic illustration of the structure of the paper@QDs@PC-MIPs component. structure and the sensing principle of paper@QDs@PC-MIPs base component. The filter paper substrates were used as base materials for the main component of the μ PADs because paper is composed of a 3D cellulose fiber that provides a good supporting base and the hydroxyl group of cellulose can be easily modified. The paper component was cut into a square piece of 8 mm $\times$ 8 mm. This bare paper was first bathed in a 0.2 M hydrochloride solution for 30 min to activate the abundant OH groups on each hydroglucose unit of the filter paper. Next, 200 μ L APTES was added to a 20 mL mixture of ethanol and water (50%, v/v) and the paper was immersed in this solution for 2–4 h to graft amino groups onto the paper. Excess amino was then removed by rinsing three times with ultrapure water. The fluorescent filter paper substrate was fabricated using an amidation reaction between the amino groups on the paper and the carboxyl groups of TGA-capped CdTe QDs. Solutions of 20 mg/mL EDC and 10 mg/mL NHS were prepared with MES buffer (pH = 5.2), and 10 mL TGA-capped CdTe QDs, 6 mL EDC, and 6 mL NHS were thoroughly mixed by ultrasonication for approximately 10 min.

The paper with abundant amino groups was immersed in this solution and incubated in the dark at room temperature for 12 h to yield the fluorescent CdTe QDs filter paper substrate (QDs @paper). Next, the functional monomer (APTES), template molecule (phycocyanin), cross-linker (TEOS), and catalyst ($\text{NH}_3 \cdot \text{H}_2\text{O}$) were added to form the imprinted silica shell on the surface of paper@QDs. In the presence of phycocyanin, a Meisenheimer complex would be produced between phycocyanin and amino groups on the CdTe QDs of the paper fiber; hence, the photoluminescent energy of QDs would be transferred to the complex and result in QD fluorescence quenching (shown in Figure 2). When the template molecule is removed, the fluorescence intensity is restored.

To evaluate the modified morphologic structures of the paper, images of bare filter paper substrate, paper@QDs, and paper@QDs@MIPs were obtained by SEM. As shown in Figure 3a, the filter paper showed a nonuniform internal cellulose structure. Figure 3b shows that the cellulose paper surface wrapped with the quantum dots had a highly uniform spherical morphology, illustrating that CdTe quantum dots had been grafted on the paper fiber surface and that these CdTe quantum dots were evenly distributed on the cellulose paper. As shown in Figure 3c, the surface had an obvious molecular imprinting layer, modified by the sol gel method. After modification (as shown in Figure 3e), the imprinting paper chips still had good fluorescence properties. Figure S2 showed FT-IR spectra of bare paper, paper@QDs, and paper@QDs@PC-MIPs samples, respectively. The results revealed that QDs and MIPs were grafted successfully.

Fabrication of 3D Microfluidic Paper-Based Chip Device. The three-dimensional PQP-MIPs μ PADs design is shown in Figure S3. Briefly, the dimensions of the chip were 5.5 cm $\times$ 2.7 cm, the sample reservoir was 6 mm in diameter, and the distance between the sample reservoir and the detection area (8 $\times$ 8 mm²) was 1.2 cm. The 3D μ PADs were composed of three layers (Figure S4, in Supporting Information). The top layer was set with a central sample reservoir connected to fluid channels that led to the paper@QDs@PC-MIPs component at the bottom layer. The wax hydrophobic barrier helped the fluid wick from the sample reservoir into the detection area by capillary forces. The middle layer was printed with wax in advance, and then an 8 $\times$ 8 mm² cavity was gauged by the knife, cutting to fit for assembly of the paper@QDs@PC-MIPs component, as discussed above. The third layer was fully patterned with wax and then attached to the paper@QDs@PC-MIPs component (shown in Figure S4a,b) to maintain good contact with the square area of the top layer. Finally, the 3D μ PADs were assembled using the clamps (Figure S4c). The 3D origami μ PADs are very simple and easy to fabricate. Moreover, some water samples are not clean and require the filtration of the pretreatment process, as shown in Figure S5, when the phycocyanin sample flowed through the channel and reached the paper@QDs@PC-MIPs, the Meisenheimer complex was generated between the phycocyanin and the amino groups on the CdTe QDs, resulting in energy transfer to the complex with quenching of QDs fluorescence. Light at wavelength 396 nm excited the fluorescence of paper@QDs@PC-MIPs that was set through the solid sample holder, and the fluorescence spectra of PQP-MIPs μ PADs were recorded using a spectrofluorometer (Fluoromax-4, HORIBA). It was noticed that the fluorescence intensity of the paper chip recovered remarkably after eluting three times, proving that the elution of the template molecule

was complete without interfering with the fluorescence (as shown in Figure S6).

Detection of Phycocyanin. The amino groups of functional monomer (APTES) molecules and the carboxyl groups of phycocyanin have a strong hydrogen bonding interaction (Figure S7). QDs for protein detection are mainly based on the electronic transfer caused by fluorescence quenching and surface adsorption. The amination reaction was carried out by APTES through covalent Si–O bonds with the hydroxyl groups of cellulose on the surface of the paper fiber. As illustrated in Figure 2, if there is no template molecule on the surface of QDs, the electrons of QDs can accept the UV energy and will be excited. Subsequently, when the excited electrons return to the ground state the quantum dot will emit green fluorescence. It is important to note that if the energy level of phycocyanin is higher than that of CdTe quantum dots, when the excited electrons of QDs return to the ground state, they will not generate fluorescence. Therefore, adsorption of more phycocyanin molecules onto the surface imprinting sites will result in greater fluorescence quenching. We further investigated the PC dynamic equilibrium curve that illustrated

Figure 4. (a) Effect of pH on fluorescence intensity changes of paper@QDs@PC-MIPs. (b) Fluorescent quenching changes of paper@QDs@PC-MIPs within 30 min. The excited light wavelength and the emission wavelength were 396 and 550 nm, respectively ($n = 5$).

Figure 5. (a) Calibration curve of fluorescence spectra of paper@QDs@PC-MIPs. The concentration of phycocyanin was spiked at 10, 20, 30, 40, and 50 mg/L. (b) Calibration curve of fluorescence spectra of paper@QDs@PC-NIPs. The inset graphs show corresponding Stern–Volmer plots of the molecularly imprinted polymer (MIP) and nonimprinted polymer (NIP). The experimental conditions were pH = 7.0 under room temperature. The excited light wavelength and the emission wavelength were 396 and 550 nm, respectively, and the slit widths of emission and excitation were 5 nm ($n = 5$).

that all the PC was absorbed by the sensors if the concentration of PC is lower than 150 mg/L (displayed in Figure S8). If the phycocyanin protein is lower than 50 mg/L, the PC could be quantitatively detected in the linear range on our paper@QDs@PC-MIP μ PADs. Therefore, when the quenching constant remains the same, the phycocyanin concentration shows a positive correlation with the fluorescence quenching value. Phycocyanin concentration can be realized by the change in the fluorescence of phycocyanin detection.

The quenching effect can be achieved by Stern–Volmer equation fitting.^{43,44}

$$(F_0/F) - 1 = K_{SV}C_M \quad (1)$$

where F_0 and F represent the fluorescence intensity in the absence and presence of quencher, respectively; C_M is the template concentration; and K_{SV} is the quenching constant for the quencher. Therefore, the ratio of $K_{SV,MIPs}$ to $K_{SV,NIPs}$ is defined as the imprinting factor (IF), and $(F_0/F) - 1$ is defined as the quenching amount. IF is one of the important parameters for characterization of molecularly imprinted polymer selectivity.

For qualitative detection of phycocyanin on 3D origami PQP-MIPs μ PADs, the fluorescence performance of the phycocyanin was strongly dependent on variables such as pH, response time, and the fluorescence stability. These relevant variables are discussed below. As shown in Figure 4a, when the pH value was less than 6.0, the changes in fluorescence intensity were lower. The fluorescence intensity increased greatly with the increase in pH value from 6 to 7, and the signal reached a maximum at pH 7. When pH value was higher than

7.5, the interaction between the template phycocyanin and the imprinted shells decreased, leading to a dramatic decline in the signal. Considering application in actual samples, 0.01 mol/L PBS buffer solution with pH = 7.0 was chosen for further experiments.

To evaluate accessibility to binding sites, dynamic adsorption was also investigated over 30 min. As seen from Figure 4b, the fluorescence intensity at 550 nm decreased within 25 min when the concentration of PC was 100 mg/L, after which the adsorption curve plateaued for the remaining 25 min. Therefore, 25 min was chosen as the response time for further experiments.

The performance of the developed PQP-MIPs μ PADs for quantitative determination of phycocyanin was further investigated. The response of the PQP-MIPs assay to increasing amounts of phycocyanin is illustrated in Figure 5a. A linear increase in response for phycocyanin amounts ranging 10–50 mg/L corresponds to a dynamic range of 1 order of magnitude. As displayed, the fluorescence intensities decreased dramatically with the increase in phycocyanin concentration, and this phenomenon contributed to the quenching effect. The error bars indicated small RSDs for five repeated measurements ($R^2 = 0.988$). The limit of detection (LOD) of the assay without any amplification steps was found to be 2 mg/L (calculated from 3σ). The RSD of measurements was 4.56% calculated from five independent experiments. The paper@QDs@PC-MIPs displayed a relatively sensitive response for phycocyanin. As shown in Figure S9, fluorescence values were determined for 20 different positions on the same piece of paper and the RSD of 4.7% showed satisfactory reproducibility of paper@QDs@

PC-MIPs. Negative controls were also performed in a similar manner using nonimprinted polymers instead of the phycocyanin-imprinted polymers. The same amount of 30 μL DI water was added dropwise to the detection area to avoid the humidity change. Compared with the NIP results (Figure 5b), in the same concentration range the fluorescence intensities with the MIPs decreased significantly, indicating that specific recognition sites with predetermined selectivity for phycocyanin were formed in the PQP-MIPs μPADs . In addition, we implemented fluorescence detection for five different paper@QDs@PC-MIPs μPADs over 7 days. As shown in Figure S10, there were no obvious differences between the results and it indicated storage stability for the paper devices.

Selectivity and Analysis of Real Environmental Water Samples. To evaluate the specific recognition ability of paper@QDs@PC-MIPs for phycocyanin, several proteins—PE, BSA, BHB, and spirulina—were chosen for the selectivity experiments. As seen from Figure 6, the amount of fluorescence

Figure 6. Selectivity of paper@QDs@PC-MIPs and paper@QDs@NIPs for solutions of different proteins (phycocyanin [PC], phycoerythrin [PE], BSA, BHB, and spirulina) at equal concentrations. The concentration of molecularly imprinted polymers or non-imprinted polymers was 10 mg/mL ($n = 7$).

quenching of the paper@QDs@PC-MIPs was the largest for phycocyanin, followed by phycoerythrin and spirulina powder. This phenomenon was mainly due to the very similar structures of phycoerythrin and phycocyanin. Moreover, spirulina powder contained a certain amount of phycocyanin and phycoerythrin, and therefore the quenching effect was observed. BSA and BHB have a different space configuration and molecular mass. They may form hydrogen bonds with functional monomer APTES, but are not complementary to the recognition sites that significantly affect the induced fluorescence. Therefore, the PQP-MIPs μPADs showed high selectivity toward the template phycocyanin.

Finally, real water samples were used to validate the practical applicability of the PQP-MIPs μPADs for detection of phycocyanin. Lake water samples and seawater samples were taken from Yantai University and the fisherman's wharf of the Yellow Sea located in the coastal zone area of Yantai City, respectively. All water samples were filtered through 0.45- μm PTFE syringe filters (Phenomenex, USA) with Na_2HPO_4 – NaH_2PO_4 buffer solution to adjust pH to 6.5–7.5. The seawater samples were diluted 100-fold before use. Different concentrations of phycocyanin (10, 20, 30 mg/L) were spiked

into the water samples without any treatment. The experiment was carried out five times with addition of the standard phycocyanin to the samples. As illustrated in Table 1,

Table 1. Recovery of Spiked Phycocyanin in Lake Water and Seawater Detected Using Paper@QDs@PC-MIPs μPADs ^a

sample	added (mg/L)	value (F_0/F)	detected (mg/L)	recovery RSD (%)
Seawater	10	0.091	9.91	99.1 $\pm$ 5.7
	20	0.201	21.14	105.7 $\pm$ 4.5
	30	0.271	28.29	94.3 $\pm$ 3.6
Lake water	10	0.085	9.31	93.1 $\pm$ 5.1
	20	0.209	21.34	106.7 $\pm$ 4.3
	30	0.279	29.10	97.1 $\pm$ 3.3

^aData show detected values and relative standard deviations (RSD, %, $n = 5$) for spiked phycocyanin.

satisfactory results were obtained with 94.3–105.7% recovery and RSD of 3.6–5.7% for the spiked seawater samples, and 93.1–106.7% recovery with RSD of 3.3–5.1% for the spiked lake water samples, respectively. The results demonstrated that our newly developed fluorescent sensor could be successfully used for the detection of phycocyanin in environmental water samples.

CONCLUSIONS

In this study, we proposed a novel kind of quantum dot wrapped with molecularly imprinted polymers on 3D origami paper-based microfluidic chip devices that provided a robust and facile route to detect phycocyanin. It can graft quantum dots on the paper through synthesizing paper@QDs@PC-MIPs components and realizing the liquid phase of QDs@MIPs being transferred to the solid-phase paper base. To the best of our knowledge, this is the first demonstration of the concept of combining QDs and MIPs directly on paper's cellulose and assembling it into the origami paper microfluidic devices. The approach offers many attractive advantages such as portability, disposability, low cost, and user-friendly protocol due to the paper's unique characteristics.

The method showed good performance with reproducible results. Successful analysis of real samples of phycocyanin in local lake water and seawater showed good sensitivity and reliability. Moreover, the 3D origami μPADs device shows great potential and versatility for detection of other different kinds of proteins using appropriate template molecule.
