Effective uptake of submicrometre plastics by crop plants via a crack-entry mode

Lianzhen Li[1,2], Yongming Luo [1,2,3] ✉, Ruijie Li[1], Qian Zhou[1], Willie J. G. M. Peijnenburg[4,5], Na Yin[1], Jie Yang[3], Chen Tu[1,2] and Yunchao Zhang[1]

Most microplastics are emitted, either directly or via the degradation of plastics, to the terrestrial environment and accumulate in large amounts in soils, representing a potential threat to terrestrial ecosystems. It is very important to evaluate the uptake of microplastics by crop plants because of the ubiquity of microplastics in wastewaters often used for agricultural irrigation worldwide. Here, we analyse the uptake of different microplastics by crop plants (wheat (*Triticum aestivum*) and lettuce (*Lactuca sativa*)) from treated wastewater in hydroponic cultures and in sand matrices or a sandy soil. Our results provide evidence in support of submicrometre- and micrometre-sized polystyrene and polymethylmethacrylate particles penetrating the stele of both species using the crack-entry mode at sites of lateral root emergence. This crack-entry pathway and features of the polymeric particles lead to the efficient uptake of submicrometre plastic. The plastic particles were subsequently transported from the roots to the shoots. Higher transpiration rates enhanced the uptake of plastic particles, showing that the transpirational pull was the main driving force of their movement. Our findings shed light on the modes of plastic particle interaction with plants and have implications for crops grown in fields contaminated with wastewater treatment discharges or sewage sludges.

Approximately 330 million tons of plastic were produced worldwide in 2015, and this figure continues to increase[1]. As a result, the contamination of our environment with plastics of all sizes is becoming one of the most widespread and long-lasting anthropogenic changes to the biosphere of our planet[2]. Microplastics (MPs) are generally defined as plastic particles in the size range of 100 nm to 5 mm, including submicrometre (100 nm to 1 μm) and micrometre (1 μm to 5 mm) plastics, and nanoplastics ranging from 1 nm to 100 nm (ref. [3]). Furthermore, MPs are separated into primary MPs, which are originally manufactured in a particularly small size for specific applications, and secondary MPs, originating from the fragmentation of larger plastic debris by external forces[3].

Scientific research on MPs pollution is rapidly advancing. However, studies to date have focused almost exclusively on aquatic systems, especially the oceans[4–6]. The oceans represent the ultimate sink for most MPs, but the terrestrial environment is a major recipient of plastics of all sizes, owing to the large amounts of anthropogenic wastes derived from sewage sludges, organic fertilizers, plastic mulching, wastewater irrigation and other sources such as atmospheric particulate deposition[7–9]. On the basis of emissions data, it is estimated that 110,000 and 730,000 tons of MPs are added annually to farmlands in Europe and North America, respectively[10]. These figures exceed the estimated annual global burden of MPs in ocean surface waters of 93,000–236,000 tons[11]. Hence, there is a great need to understand and quantify the distribution, fate and transformation of MPs in the terrestrial compartment.

Very little information exists on the accumulation and effects of MPs on soil biota[12,13]. Plants comprise a basic living component of terrestrial ecosystems and are an important source of human food. Thus, understanding the interactions between MPs and plants is

crucial. Given the central role of agroecosystems in food production and the tight connection with soil biodiversity, the accumulation of MPs in the terrestrial environment provides various potential pathways for the exposure of humans and biota to MPs and might induce adverse effects on organisms (including food crops) and human health[4,5]. Understanding the interactions of MPs with plants, particularly food plants, is thus a crucial aspect of risk assessment for these materials. In addition, the use of treated wastewater for irrigation is increasing worldwide and is not limited to arid zones[14]. Considering the ubiquity of plastic beads in treated wastewater[15], it is important to evaluate their uptake by edible crops under natural conditions.

Despite the large body of literature on the apoplastic uptake of nanomaterials[16], it has been assumed that MPs are too large to pass through the physical barriers of intact plant tissue and hence cannot be internalized directly into plant tissue. The Casparian band of the root endodermis is believed to function as a barrier to the apoplastic movement of chemicals and water into the root stele. However, there are known to be discontinuous regions in the Casparian band in roots, through which unhindered transport in the apoplast might occur. Such regions are found at the root tip where the endodermal cells are not yet mature[17] and at the sites of secondary root initiation[18]. Given that such openings are a known pathway of infection by plant pathogens or bacteria (with submicrometre widths, and lengths variable to several micrometres), known as the crack-entry mode[19,20], we hypothesized that these openings might provide routes for plastic particle uptake.

Here, we aim to determine whether wheat and lettuce growing in hydroponic systems and sand matrices or a sandy soil are able to take up submicrometre- to micrometre-sized plastic beads from either a nutrient solution or treated wastewater and translocate

Fig. 1 | Accumulation of 0.2 μm fluorescently labelled PS beads by wheat plants. Two-week-old plants were exposed to 50 mg l⁻¹ suspensions of PS beads labelled with NB and PS beads labelled with NBD-Cl for 10 d. The uptake of PS beads by wheat roots, stems and leaves was analysed under bright field conditions and in red/green channels using confocal laser scanning microscopy. **a–c**, Bright field images showing transverse sections of a root (**a**), a stem (**b**) and a leaf (**c**) from a whole wheat plant treated with PS beads labelled with NB and PS beads labelled with NBD-Cl. **d–f**, Images of wheat root (**d**), stem (**e**) and leaf (**f**) transverse sections observed using either the red or green channel to detect NB or NBD-Cl, respectively. **d**, Observation of aggregates of PS beads labelled with NB in the intercellular spaces of the epidermis and xylem and the flow of PS beads labelled with NB towards the cortex. **e**, PS beads labelled with NBD-Cl observed in the vascular tissue of the stem. **f**, The accumulation of the fluorescent aggregates in the xylem and associated cells in the vascular tissue of the leaf. **g–i**, The corresponding merged images of **a** and **d** (**g**), **b** and **e** (**h**), and **c** and **f** (**i**). Scale bars, 50 μm.

these particles from roots to shoots, and if so, to identify the uptake sites and pathways. Wheat was chosen as a representative of monocot plants because it is one of the main staple foods worldwide; lettuce was selected as a representative of dicot plants because it is a popular leafy vegetable.

Polystyrene beads penetrating the stele via a crack-entry mode

Two fluorescent dyes were used to detect the presence of plastic beads because the red fluorescence from Nile blue (NB) is indistinguishable from the autofluorescence emitted by chloroplasts, and the green fluorescence from 4-chloro-7-nitro-1,2,3-benzoxadiazole (NBD-Cl) is indistinguishable from the autofluorescence in root tissues of wheat and lettuce plants (Supplementary Figs. 1 and 2). Sections from untreated control wheat and lettuce plants showed no detectable autofluorescence at specific excitation wavelengths (Supplementary Fig. 3). The roots of wheat grown in a Hoagland solution containing 0.2 μm polystyrene (PS) beads showed clear concentration-dependent fluorescence (Supplementary Fig. 4). Fluorescence was observed in the roots, shoots and leaves of wheat and lettuce exposed to 0.2 μm PS beads (Figs. 1 and 2) and in the roots

of wheat and lettuce exposed to 2.0 μm PS beads (Supplementary Fig. 5). Very few luminescence signals were observed in the vascular system or in the epidermis of wheat and lettuce roots for 5.0 μm and almost none for 7.0 μm and 10 μm PS microbeads (Supplementary Fig. 6). Our main study investigated the uptake of submicrometre-sized (0.2 μm) and micrometre-sized (2.0 μm) plastic beads to explore the underlying mechanisms involved in plastic bead uptake and transport.

After attaching to the border cells, submicrometre PS beads (0.2 μm) were observed along the entire lateral root cap and within the apical meristem of wheat and lettuce roots (Supplementary Figs. 7 and 8). We suggest that the entrapment of PS beads in the root cap mucilage promoted their penetration of the cell wall, enabling diffusion through the apical meristem tissue, which is highly porous because of active cell division[21]. However, cell wall pores (3.5–5.0 nm)[22] and intercellular plasmodesmata (50–60 nm at the midpoint)[23] have diameters that are smaller than the 0.2 μm diameter of the PS beads used in this study. We therefore suggest that PS beads can enter the apical meristem only by passing through the epidermal layers of the intact apical root sections, where the Casparian band is not fully developed[21]. The PS beads then diffuse across the apoplastic spaces in the apical zone into the root xylem vessels, which facilitated their rapid transport in wheat roots (Supplementary Fig. 9). Confocal images of the transverse sections of wheat revealed that the PS luminescence signals were located mainly in the vascular system of the roots and stems (Fig. 1) and were visible in the xylem vessels and epidermis after 2 h (Supplementary Fig. 10). After 12 h, PS beads were detected in the wheat cortical tissue (Supplementary Fig. 10), whereas in lettuce plants, they appeared to be more restricted to the vascular tissues (Fig. 2 and Supplementary Fig. 11). Fluorescence was observed mainly along cell walls and in the intercellular region, indicating that 0.2 μm PS beads entered the cortical region through gaps between epidermal cells but were not able to penetrate the endodermis in regions where the Casparian band was continuous. A strong PS luminescence signal was detected in cracks in the lateral root zone (50–100 mm from the apex) (Supplementary Fig. 11), where the lateral roots penetrate the endodermis and the cortex, indicating that these cracks were major entry sites into the wheat and lettuce root xylem for submicrometre PS beads. The physical sites of the apoplasmic bypass were located not only in regions where lateral roots emerge but also in the lateral roots themselves. This is supported by the observation of beads penetrating into the xylem of lateral roots as well as their presence in the primary roots of wheat and lettuce (Supplementary Fig. 11e,f).

In contrast to the 0.2 μm PS beads, micrometre-sized PS beads (2.0 μm) penetrated the stele only when a secondary root that had just emerged through the epidermis of the main root was present (Supplementary Fig. 4), consistent with observations that 2.0 μm microbeads were not present in the entire wheat roots lacking secondaries (Supplementary Fig. 12). Lateral root formation occurs deep within the primary root. To allow lateral root primordia to emerge, the overlying tissues undergo cell separation, resulting in gaps between the epidermal cells at sites of lateral root emergence. We visualized these gaps in lettuce and wheat roots by performing scanning electron microscopy (SEM) (Supplementary Fig. 13) and by scanning root samples using a high-resolution X-ray computed microtomography system to construct three-dimensional images of wheat roots (Supplementary Fig. 14). Confocal images of longitudinal sections through a recently emerged secondary wheat root revealed that the luminescence signals from 0.2 μm PS beads were visible in the xylem vessels and cortical tissue after 30 min (Supplementary Fig. 15), whereas 2.0 μm PS beads were first detected in the epidermis and vascular tissues of wheat after 48 h (Supplementary Fig. 15). After 12 h, strong luminescence signals from the 0.2 μm PS beads were observed in the stele of the secondary
Root Petiole Leaf

Fig. 2 | Accumulation of 0.2 μm fluorescently labelled PS beads by lettuce. One-month-old plants were exposed to 50 mg l⁻¹ suspensions of PS beads labelled with NB and PS beads labelled with NBD-Cl for 10 d. The uptake of PS beads by lettuce roots, petioles and leaves was analysed under bright field conditions and in red/green channels using confocal laser scanning microscopy. **a–c**, Bright field images showing transverse sections of a lettuce root (**a**), a petiole (**b**) and a leaf (**c**) treated with PS beads labelled with NB or PS beads labelled with NBD-Cl. **d–f**, Images of lettuce root (**d**), petiole (**e**) and leaf (**f**) transverse sections observed in the red or green channel to detect NB or NBD-Cl, respectively. **d**, Aggregates of fluorescently labelled PS beads labelled with NB in the epidermis and xylem. **e,f**, Fluorescent beads in the vascular tissue of the petiole and leaf, respectively. **g–i**, The corresponding merged images of **a** and **d** (**g**), **b** and **e** (**h**), and **c** and **f** (**i**). Scale bars, 100 μm.

root (Supplementary Fig. 15). We hypothesize that these beads entered this region via the lateral root apex. In most cases, 2 μm PS microbeads were not present in the lateral roots; however, they were observed in the main root stele after moving along the margins of the secondary root and through the region occupied by cells in the transition zone, which are cells derived from the endodermis of the main root that are transitioning between the endodermis of the main root and the epidermis of the secondary root[18]. Here, an entry mode for the PS beads was detected in which even the micrometre-sized (2.0 μm) beads penetrated the stele via cracks in the epidermis that initiate lateral root formation.

From SEM images, the aggregation of 0.2 μm PS beads was mostly in the xylem and on the cell walls of the cortex tissue in wheat and lettuce roots, indicating that the beads passed through the intercellular space via the apoplastic transport system (Figs. 3 and 4). Micrometre-sized beads were visible in the gaps between the epidermal cells of the main wheat root and the secondary root (Fig. 5). We also observed that the 0.2 μm PS beads adhered to one another and self-assembled systematically into grape-like (Fig. 4a) and string-like (Fig. 4b) clusters in the intercellular space of the lettuce root and stem vascular tissue. In contrast to the aggregation of 0.2 μm PS beads, micrometre-sized PS beads were dispersed in the tissue of lettuce plants (Fig. 6) and were visible in the crack between the epidermal tissue of the main wheat root and the secondary root

Fig. 3 | SEM images of 0.2 μm PS bead localization in the root, stem and leaf of a wheat plant. Two-week-old plants were exposed to 50 mg l⁻¹ suspensions of PS beads for 10 d. **a**, PS beads deformed and squeezed into the intercellular space of the vascular tissue of the root. **b**, Aggregated clumps of PS beads on the outer side of the cell wall in the stem xylem. **c**, PS beads were observed to associate with other cellular materials in the leaf vein. (Fig. 5a,b) and thereby moved through the pericycle and into the xylem (Fig. 5c,d).

Once inside the central cylinder, particles can move towards the aerial parts of a plant through the xylem, following the transpiration stream. The 0.2 μm and 2.0 μm beads were present in the xylem sap (Supplementary Fig. 16) of wheat and lettuce exposed to a 50 mg l⁻¹ suspension of PS beads, showing that both submicrometre-sized and micrometre-sized plastic beads were transported from roots to shoots via the transpiration stream. The fluorescence intensity was stronger at the junction of the primary root and the secondary root in wheat under high transpiration conditions than under low transpiration conditions (Supplementary Figs. 15 and 17), demonstrating that an increase in the transpiration rate enhances bead uptake by the plant. This finding suggests that the plant transpirational pull plays an important role in the uptake and translocation of plastic beads.

We also grew plants in a sand matrix or a sandy soil with different concentrations of PS beads. Sand was used as a proxy for soil because plants grown in sand develop similar root morphologies
Fig. 4 | SEM images of 0.2 μm PS bead localization in the root and leaf of a lettuce plant. One-month-old plants were exposed to 50 mg l⁻¹ suspensions of PS beads for 10 d. **a,b**, Beads were detected as systematically aggregated clumps in a grape-like or chain-like shape in lettuce roots. **c**, PS beads were observed to associate with other cellular materials in the leaf veins of lettuce plants. The insets show enlargements of the areas indicated by the red squares.

as plants grown in soil. Furthermore, the mechanical impedance and water stress experienced by plants growing in sand and soil are similar. Both submicrometre (0.2 μm) and micrometre-sized (2.0 μm) PS beads can be seen to enter the xylem vessels at the lateral root emergence sites (Supplementary Figs. 18–20) in sand cultures and were also present in the xylem sap of wheat and lettuce (Supplementary Fig. 21). The accumulation of 0.2 μm fluorescently labelled PS beads was observed in the roots of wheat grown for 20 days with 500 mg kg⁻¹ of beads in a sandy soil (Supplementary Fig. 18). Nevertheless, after solid exposure we did not detect the entry of 0.2 μm beads into the steles from the root apex as observed in hydroponic exposure. Compared with the solid culture, the hydroponic culture depressed root apoplastic barrier formation to increase oxygen delivery to the stele from the cortical aerenchyma[24], which would facilitate the transport of plastic beads passing through the apoplastic barriers at the root tip. Furthermore, plants grown hydroponically had higher growth rates and thus higher transpiration rates, thereby providing a stronger driving force for the apoplastic translocation of beads.

Uptake and transfer of plastic beads from treated wastewater

Polymethylmethacrylate (PMMA) is among the most commonly used plastic types as beads in cosmetics in Europe and in other countries[25,26]. PMMA beads are likely to be transported to wastewater treatment plants. It is anticipated that a substantial proportion will pass through filtration systems due to their small size, and subsequently enter the environment[27]. The uptake of PMMA beads was evaluated in treated wastewater using lettuce plants. Confocal microscopic images demonstrate that PMMA (0.2 μm) fluorescence was observed in the epidermis as well as in the vascular systems of different root zones (Supplementary Fig. 22). However, a much higher intensity of fluorescence appeared at the primary root–lateral root junction of lateral root emerging sites than in other regions (Supplementary Fig. 22). Fluorescence from 2.0 μm PMMA microbeads was located mainly at the lateral root emerging sites (Supplementary Fig. 23). The fluorescence was also observed in the intercellular space in lettuce leaf veins (Supplementary Fig. 24). The fluorescence patterns of these plastic beads in treated wastewater were similar to the patterns of PS beads in the nutrient solution. Furthermore, the fluorescence was more intense in plants under high transpiration regimes than in plants under low transpiration regimes in treated wastewater (Supplementary Figs. 22–24), verifying that an increase of the transpiration rate enhances the uptake of PMMA beads from treated wastewater by lettuce. This confirms that a higher temperature and lower humidity result in greater transpiration rates and thus an increased accumulation of beads of different polymer types in the root and upper portions of lettuce. On the basis of this finding, we hypothesize that in arid and hot climates where irrigation with treated wastewater is common, submicrometre plastic beads in wastewater may have a greater tendency to accumulate in crop plants due to the relatively high plant transpiration rates. Subsequent SEM observations showed that no beads can be found around the root and leaf veins in the control group without plastic bead treatments (data not shown). However, SEM images of cross sections in the root tissue clearly showed the presence of 0.2 μm PMMA beads that were agglomerated and formed relatively larger clusters in the intercellular space of the vascular system as well as in the primary root–lateral root junction areas (Supplementary Fig. 25). Distinct from the 0.2 μm PMMA beads, the 2.0 μm beads were observed as single particles in the xylem vessels and the crack between the epidermal tissue of the primary lettuce root and the secondary root (Supplementary Fig. 26). The PMMA beads and their aggregates were also observed in the epidermis of lettuce roots (Supplementary Figs. 25 and 26). The presence of PMMA beads in the leaf vein (Supplementary Figs. 25 and 26) demonstrated the transfer of beads from the root to the shoot in lettuce.

Wheat plants were further studied in sand matrices irrigated with treated wastewater spiked with PS beads. Confocal microscopic images showed that both submicrometre (0.2 μm) and micrometre-sized (2.0 μm) PS beads enter the xylem vessels at the lateral root emergence sites of wheat (Supplementary Figs. 27 and 28). However, the 2.0 μm PS beads could not enter the epidermis or the cortex in the root apex. SEM studies revealed that PS beads were present in the root vascular systems and at the primary root–lateral root junction (Supplementary Fig. 29). Both sizes of beads were also detected in the xylem sap of wheat (Supplementary Fig. 30), indicating that PS beads transfer from the roots to the shoot via the vascular system.

Features of polymeric beads for their uptake and transfer

For uptake and translocation in plants, particulate matter must cross a series of chemical and physiological barriers, which control the size exclusion limits (SELs). The thickness and architecture of these barriers vary with species, growth stages and environmental conditions[28]. It is generally accepted that very large nanoparticles
Fig. 5 | SEM images of 2.0 µm PS microbead localization in the root, stem and leaf of a wheat plant. Two-week-old plants were exposed to 50 mg l[-1] suspensions of PS beads for 10 d. **a,b**, PS microbeads in the crack between the epidermal tissue of the main wheat root and the secondary root. **c,d**, PS microbeads in the xylem vessels and cortical tissue. **e,f**, PS microbeads in the xylem of the stem. **g,h**, PS microbeads in the leaf vein. **b,d,f,h** are enlargements of the areas marked by the red squares in **a,c,e,g**, respectively. In **b** and **h**, the red arrows indicate the microbeads.

(over 100 nm) can be taken up by plants despite the very small SELs (less than 20 nm) of plant roots. Our findings showed the effective accumulation of submicrometre PS particles (200 nm) in the root. Another study also showed promising results for the root uptake of zein nanoparticles (up to 135 nm; ref. [29]). By contrast, the typical upper size limits for inorganic nanoparticles are always up to 50 nm for root uptake[30–32]. Our own experiment using 200 nm silica fluorescent nanoparticles showed no nanoparticle uptake inside the root tissue, although a few light-red particles adhered to the root surface (Supplementary Fig. 29). This difference in SEL between metal-based particles and polymeric particles may be at least partly attributed to the intrinsic features (density, hydrophobic surface, adhesive properties and mechanical flexibility) of the polymeric particles, which presumably enable irreversible adsorption on the cellulosic cell wall[33]. The root cap can secrete large amounts of mucilage (a highly hydrated polysaccharide) to defend the plant against pathogen attacks[34]. We observed that PS beads were extracellularly trapped in the wheat root cap mucilage (Supplementary
Fig. 6 | SEM images of 2.0 μm PS bead localization in the root and leaf of a lettuce plant. One-month-old plants were exposed to 50 mg l[-1] suspensions of PS beads for 10 d. **a,b**, Microbeads in the root xylem. **c,d**, PS microbeads in the leaf vein. **b,d** are enlargements of the areas marked by the red squares in **a,c**, respectively.

Figs. 7 and 8). The negative charges on the bead surface did not prevent interactions with the roots, whose surface and mucilage are also likely to be negatively charged[35]. The washing procedures undertaken before analysis did not remove all the PS beads present on the root surface, demonstrating that the beads adhered strongly to the root surface. Hence, it is proposed that in addition to the role of mucilage, hydrophobic interactions dominate PS bead adhesion at the root surface, owing to the high level of hydrophobicity of both the PS beads and the cellulose cell wall[36]. The PS beads were observed to be deformed in the intercellular space of wheat root during the incorporation process (Supplementary Fig. 32), although it cannot be completely ruled out that the deformation is caused by the SEM sample preparation process. The mechanical strength (Young's modulus) of these PS beads (2.1 GPa) was lower than the values usually reported for plant cell walls (Supplementary Fig. 33, ref. [37]). As a result, the PS beads compress and deform on adsorption and intercellular internalization because they are less stiff than the plant cell walls. We suggest that this intrinsic property is essential for the migration of plastic beads within plant tissues, enabling them to reach the root central cylinder and the vascular tissues and resulting in their upward movement to the aerial parts of the plant. The role of the mechanical properties of polymeric nanoparticles in their bio–nano interactions has recently been recognized as a key feature in modulating the fate of polymer nanoparticles for drug delivery[38].

Tracking methodology for polymeric particles
Fluorescence labelling and SEM imaging can be used to investigate the localization of plastic beads in plants[39]. Fluorescence tracking of particles is not a perfect technique, but it is one of the best currently available methods for tracking non-metallic nanoparticles. The chemical incorporation of fluorescent dyes into the polymer network minimizes the risk of dye leaching. We have monitored the potential dye leaching from PS and PMMA beads in the exposure medium using a centrifugal ultrafiltration technique over an

exposure duration of 10 days. In most cases, no dye leakage was detected in the exposure medium for PMMA beads. Over time, there was only a minimal increase of NBD-Cl release from the PS beads into the solution (Supplementary Fig. 34). Consequently, the presence of fluorescent markers in the aqueous phase can be assumed to be quite negligible. However, it should be noted that in many cases dye leaching in vivo cannot be predicted by in vitro testing using culture media, because the composition of biological fluids outside and inside cells is more complex. Here, the observed fluorescence within the tissue was taken as an initial observation. SEM observation was then used to identify the presence of plastic beads in the plant tissues on the basis of size and morphology, although this method still cannot with full certainty confirm whether the observed particles are actually PS or PMMA.

Exposure and environmental implications
This study showed the ubiquitous effective root accumulation of different submicrometre plastic particles on exposure to irrigation wastewater. The potential risk of MP uptake via consumption may therefore be substantially greater for root vegetables such as carrots, radishes and turnips. Once MPs enter plant roots, they can translocate to different organs. The extent of the translocation of MPs depends primarily on the transpiration stream, where a compound moves with the water flow through the xylem to the sites of greatest transpiration[40]. Our results confirmed that higher temperature and lower humidity result in greater transpiration rates and thus increased accumulation of beads of different polymer types in the root and upper portions of two crop plants. Furthermore, the presence of MPs in crop plants could increase the direct exposure of humans to plastic-associated chemicals (including leachable additives and adhering contaminants). Lettuce is one of the most consumed vegetables around the world[41]. In the European Union, the daily consumption of 22.5 g of lettuce per person represents around 6.5% of the total dietary intake of vegetables[42]. This possibility is of particular concern, especially in the case of lettuce cultivated in

hydroponic greenhouse systems containing MPs originating from irrigation water and nutrient-rich fertilizer solutions.

Our experiments were performed with MPs concentrations of several mg l^{-1} to depict the underlying uptake mechanisms. It remains challenging to conclude that the experimental exposures in this study are likely to mimic environmental conditions in terms of MP contamination, since the available analytical methods do not yet permit the accurate detection of nano-sized and even submicrometre-sized plastic particles in the environment. The production, emission and leakage of plastics into the environment are expected to increase by an order of magnitude within the next decade, and MPs concentrations are expected to increase, if only on the basis of the assumption of a steady rate of fragmentation of plastic debris[1]. Despite the fact that the MPs detected in the environment and found in soils are in the range of tens to hundreds of micrometres[7,8], it is now commonly accepted that plastics present in the environment (including in soils) will be degraded, depending on the environmental conditions, to smaller particles[43–46]. This includes the formation of particles in the low-micrometre to nanometre size range. Here, we tested different sizes of manufactured PS and PMMA beads, which may behave differently from environmental MPs because of differences related to the polymer type, size, coating and shape. Future investigations should therefore include both beads (or other approximately spherical particles) and fibres commonly observed in the environment[47].

This study revealed the ability of higher plants to accumulate and translocate submicrometre- and micrometre-sized MPs. The results highlight that the crack-entry mode needs to be considered as an important mode of interaction of small MPs with plants. Root openings that develop as a consequence of aging, as well as damage by below-ground herbivores and mechanical injury, might also provide entry sites for MPs. These findings warrant the urgent consideration of new management strategies to control the release of MP waste products in terrestrial environments in discussions of global plastic pollution.

Methods

PS and PMMA beads. Stock solutions of plain (without functionalization) fluorescently labelled PS and PMMA particles were custom synthesized from Daè Scientific Co., Ltd. (Tianjin, China) and Rigor Biotechnology Co., Ltd (Wuxi, China). They were supplied as 10 mg ml^{-1} suspensions in ultrapure water (18.2 MΩ, Millipore). The PS beads had primary nominal sizes of ~0.2 μm, 2.0 μm, 5.0 μm, 7.0 μm and 10.0 μm. The actual sizes of the 0.2 μm and 2.0 μm PS beads were determined to be 0.21 ± 0.05 μm and 1.93 ± 0.09 μm using SEM (Supplementary Fig. 35a,b). The actual sizes of the 0.2 μm and 2.0 μm PMMA beads were determined to be 0.18 ± 0.05 μm and 2.0 ± 0.1 μm using SEM (Supplementary Fig. 35c,d). The PS and PMMA beads were prepared on the basis of previously described methods[48,49]. The composition of the beads was confirmed by Raman or infrared spectroscopy (Supplementary Figs. 36 and 37). The Raman spectra of the beads were recorded using a DXR Raman microscope (Thermo Scientific). A 780 nm laser was focused by a ×10 microscope objective for the sample dried on a glass slide. Infrared spectra were recorded using a Fourier transform infrared spectrometer (FTIR, Nicolet iS5, Thermo Company) equipped with an iD7 ATR accessory and diamond crystal on a single reflection plate. The FTIR was operated with a resolution of 4 cm and a mid-infrared range of 650–4000 cm^{-1} at a rate of 32 scans per analysis. All spectra were compared with a database (Hummel Polymers and Additives, Putuzu, Thermo Fisher) to verify the composition of the plastic particles.

The fluorescent dye (NB or NBD-Cl) was chemically incorporated into the polymer network[49]. The labelled beads were centrifuged and washed three times with ethanol and deionized water to remove any free dye. To assess the stability of fluorescence, we analysed the loss of fluorescence intensity after exposure of the PS and PMMA beads in Hoagland solution[50] or treated wastewater using a centrifugal ultrafiltration technique with an exposure duration of 10 days. In the dye leakage experiment, the centrifugal filter units (Amiconultra, 3 kDa molar mass cut-off) were first pre-equilibrated with the experimental medium used for exposures. Subsequently, 4 ml of each sample were centrifuged at 3,700 g for 20 min. To ensure that adsorptive losses of dyes were negligible, both the supernatant and the filtrate were discarded, and the protocol was repeated three times. After the fourth centrifugation cycle, potential leaked dyes were determined in the filtrate. In most cases, no dye leakage was detected in the exposure medium for PMMA beads. Over time, there was a minimal increase of NBD-Cl release from the PS beads into the solutions, but the dissolved dye did not exceed 3% (Supplementary

Fig. 34). The presence of fluorescent markers in the aqueous phase can therefore be assumed to be quite negligible.

The stock suspensions were sonicated for 2 min using a sonicator (Branson Ultrasonic) and were then diluted to obtain the final bead concentrations used in the tests. The average hydrodynamic diameter and zeta potential of the PS and PMMA beads were determined by dynamic laser scattering using a Malvern Zetasizer Nano-ZS90 (ZEN3590). The average hydrodynamic diameters of the 0.2 μm and 2.0 μm PS beads were 0.25 ± 0.06 μm and 2.3 ± 0.4 μm, respectively, while the 0.2 μm and 2.0 μm PMMA beads were 0.23 ± 0.05 μm and 2.2 ± 0.3 μm in treated wastewater. The surfaces of the PS and PMMA beads were negatively charged, with the 0.2 μm PS beads having a more negative zeta potential (−36.6 ± 0.7 mV) than the PS 2.0 μm beads (−9.3 ± 0.5 mV), and the 0.2 μm PMMA beads having a more negative zeta potential (−26.0 ± 0.8 mV) than the PMMA 2.0 μm beads (−2.1 ± 0.4 mV) in treated wastewater.

Fluorescent silica nanoparticles (0.2 μm) were prepared through the covalent encapsulation of a kind of aminocyanine dye inside silica nanoparticles by reverse microemulsion[51] and were provided by a friend. The particles showed bright and stable fluorescence on excitation at 635 nm. The average hydrodynamic diameters of the particles in Hoagland solution were 0.26 ± 0.06 μm.

Plant materials and growth conditions. Seeds of wheat (*Triticum aestivum* L.) and lettuce (*Lactuca sativa* L., Rosa) were used in this study. Wheat seeds of an almost uniform size were selected and surface sterilized by treatment with a 10% NaClO solution for 5 min. The seeds were then washed three times with deionized water to remove the residual NaClO solution and were transferred to moistened filter paper and incubated in the dark at 25 °C to induce germination. After 4 d, four seedlings of uniform size were transferred to a 1 l beaker containing Hoagland solution. The beaker was covered with a cap and placed in a growth chamber at 25 ± 2 °C with an illumination of 250 μmol m^{-2} s^{-1}, a 12 h day/12 h night photoperiod and 80% relative humidity. Each box was equipped with an aquarium aerator to provide oxygen to the roots and to keep the PS beads in suspension. After 10 d, the wheat plants were exposed to different concentrations (0.5, 5 and 50 mg l^{-1}) of PS beads for up to 10 d. The experiment was repeated three times. Transpiration rates were controlled by placing the plants in one of two environmentally controlled growth chambers maintained at different ambient air water vapour pressure deficits. The water vapour pressure deficit, which is defined as the ratio of the actual air water vapour pressure to the air water vapour pressure at saturation, controls the transpiration rate[52]. The low-transpiration-rate chamber was maintained at a relative humidity of 80% and a temperature of 15 °C (a water vapour pressure deficit of 0.9). The high-transpiration-rate chamber was maintained at a relative humidity of 50% and a temperature of 30 °C (a water vapour pressure deficit of 0.7). The night temperature in both chambers was 20 °C, and the daytime relative humidity was maintained. A 12 h day with a light intensity of 250 μmol m^{-2} s^{-1} was used. Stomatal conductance (mol m^{-2} s^{-1}) and transpiration rate (mmol m^{-2} s^{-1}) were measured using an open photosynthetic system (LI-6400XTR, Li-Cor) at a photon flux density of 1,000 μmol m^{-2} s^{-1} and an ambient CO$_2$ concentration of 400 μmol mol^{-1}.

Lettuce seeds were surface sterilized with a 10% NaClO solution for 5 min and washed three times with deionized water. The seeds were then germinated and grown in organic soil (potting mix) in a greenhouse (65% relative humidity) at 25 ± 2 °C with a 16 h day/8 h night photoperiod for 21 d. The plants were removed from the soil, and the roots were carefully washed with water until no soil was visible on the surface. Two plants were allocated to a 1 l beaker containing Hoagland solution and allowed to grow for one week before treatment with PS beads. After one week, the Hoagland solution was replaced with Hoagland solution to which a 50 mg l^{-1} suspension of PS beads had been added. Plants grown in Hoagland solution that lacked a PS bead suspension were used as controls. The plants were grown for 10 d before the treatments were evaluated. Each treatment was replicated three times.

The fate of the PS beads after addition to a solid matrix was investigated using river sand or a sandy soil. River sand was sieved to obtain particles of less than 2 mm and washed thoroughly with water before drying and use. The soil was collected in summer 2017, before sowing, from the top layer (0–20 cm) of a fluvo-aquic soil in Liaocheng, Shandong province, China. The soil had a sandy loam texture (clay 5%, silt 32% and sand 63%), pH 8.2, total N 0.56 g N kg^{-1} and total organic C 8.0 g C kg^{-1}. The cropping rotation system was wheat in winter and maize (*Zea mays* L.) in summer. Triplicate sand or soil samples (300 g) were amended with a suspension of PS beads at a target concentration of 150 mg kg^{-1} sand or 500 mg kg^{-1} soil, and placed in 800 ml beakers, followed by the addition of deionized water to the sand or soil to 60% of the water holding capacity. Each beaker was covered and sealed with plastic film with small holes to maintain a relatively constant moisture content; deionized water was added every 4 d if necessary. The wheat and lettuce seedlings were planted in the sand or soil and incubated in a growth chamber (described above). Samples were collected after 20 d and immediately washed with deionized water before analysis.

Experiments on plastic bead uptake from treated wastewater. To evaluate plastic bead uptake from real wastewater, the plants were studied further in treated wastewater spiked with MPs and sand matrices irrigated with spiked treated wastewater. Treated wastewater was provided by a local municipal

wastewater-treatment facility. The treated wastewater characteristics were as follows: biological oxygen demand, $10.0\,\text{mg}\,\text{l}^{-1}$; chemical oxygen demand, $40\,\text{mg}\,\text{l}^{-1}$; total organic carbon, $56.9\,\text{mg}\,\text{l}^{-1}$; total nitrogen, $14.7\,\text{mg}\,\text{l}^{-1}$; total phosphorus, $11.9\,\mu\text{g}\,\text{l}^{-1}$; pH, 6.4; and electrical conductivity, $3.4\,\text{mS}\,\text{cm}^{-1}$. The treated wastewater was filtrated through a $0.45\,\mu\text{m}$ membrane and then was used to perform the lettuce uptake experiment in hydroponic cultures spiked with $50\,\text{mg}$ of PMMA beads per litre of culture and the wheat uptake experiment in sand culture with a concentration of $150\,\text{mg}$ of PS beads per kg of sand, as described above.

Xylem sap extraction in situ. After exposure to PS beads in hydroponic cultures and sand matrices or a sandy soil as described above, xylem samples were obtained by severing the stems of lettuce and wheat seedlings approximately $5\,\text{cm}$ above the surface of the nutrient solution. After the stem surface had been thoroughly washed with deionized water, the tissues were blotted dry, and the exudate was collected and placed on a glass slide covered with a coverslip. To determine the presence or absence of beads, the slides were examined using an Olympus-CX31 microscope (Olympus).

Confocal microscopy. After exposure to PS or PMMA beads, the roots were removed and washed thoroughly with distilled water. Samples of the roots were collected at different times using separate batches of the two plant species and were then evaluated. Subsequently, fresh root (mature zone) and stem ($2\,\text{cm}$ from the base of the stem) segments were collected and embedded in 4% agarose. The root and stem samples and the leaf blades (with the primary vein) were sectioned into 40- and 100-μm-thick sections, respectively, using a vibrating microtome (VT1200S Vibrotome, Leica). Semithin sample sections were placed on a glass slide and covered with a coverslip. A few drops of PBS were added to keep the sample hydrated. The sectioned tissue was inspected using a confocal laser scanning microscope (FluoView FV1000, Olympus) at excitation/emission wavelengths of $488/515\,\text{nm}$ and $635/680\,\text{nm}$ for NBD-Cl and NB, respectively. For each species, transverse and longitudinal sections of at least three plants per treatment group were examined before representative images were selected. The images were captured with a SPOT camera and imported into the compound microscope imaging software Fluoview (Olympus FV10-ASW, version 4.2b) (https://www.olympus-lifescience.com.cn/en/support/downloads/). The images were adjusted for brightness and contrast enhancement.

SEM. Samples from roots, stems and fully expanded leaves near the primary veins were excised, sectioned into small pieces and frozen in liquid nitrogen. The samples were then freeze-dried and coated with gold for $60\,\text{s}$ (ca. a $1\,\text{nm}$ thickness of gold) by a sputter coater (Cressington model 108, Ted Pella). The samples were then examined by a scanning electron microscope (SU8010). The cross sections were viewed at an accelerating potential of $20\,\text{kV}$ in high vacuum mode with backscatter detection. Images were captured at different magnifications. For each species, at least three plants per treatment group were examined. Digital images were captured using an EVO 40 scanning electron microscope (Zeiss). Lettuce and wheat root samples of the lateral root zone were examined with an environmental scanning electron microscope (FEI Quanta 250 FEG ESEM) operating in high vacuum mode.

X-ray computed microtomography. Root samples of the lateral root zone were scanned using a SkyScan 1172 high-resolution X-ray computed microtomography system (Bruker microCT). The settings were optimized to visualize the gaps between the epidermal cells. The X-ray source was operated at $40\,\text{keV}$ without a filter and with a $0.4°$ rotation step. A tube of samples was positioned vertically and measured using the oversize scan mode ($2.75\,\text{h}$ per sample). The measured X-ray shadow projections were digitized as $1{,}800 \times 1{,}048$ pixel 16-bit images and were processed to obtain reconstructed cross-sectional images using SkyScan NRecon v.1.5.1.4 software (http://www.skyscan.be/next/nreconcluster.zip).

Atomic force microscopy. The mechanical properties of the PS beads were analysed by performing DMT modulus measurements using a Dimension Icon atomic force microscope system (Bruker) in PeakForce quantitative nanomechanical property mapping mode. Images were collected using commercial silicon probes (RTESPA-300, Bruker) and a Stargate scanner (maximum scan size, $100\,\mu\text{m}$) at a scan rate of $0.5\,\text{Hz}$. The spring constant was calibrated using the thermal tune method. This mode was based on peak force tapping, which performed a very fast force curve measurement for every pixel in the image by modulating the Z piezo at $\sim2\,\text{kHz}$ with an amplitude of $100\,\text{nm}$. The peak force of each of these curves was then used as the imaging feedback signal. The analysis of the force curve data was performed in real time, providing a map of multiple mechanical properties such as the modulus and adhesion that had a resolution similar to that of the height image.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability
The data that support the findings of this study are available in the paper and its Supplementary Information or from the corresponding author upon request.

Author contributions

Y.L. managed the whole project, designed all the experiments and jointly wrote the manuscript. L.L. conducted the uptake experiments and wrote the manuscript. R.L. inspected the plant tissue using a confocal laser scanning microscope and collected the images. N.Y. and J.Y. examined the samples with a scanning electron microscope and collected the images. R.L. and Y.Z. conducted the X-ray computed microtomography using a high-resolution X-ray computed microtomography system. Q.Z. and N.Y. analysed the mechanical properties of the PS beads using a Dimension Icon atomic force microscope system and collected the images. W.J.G.M.P. and C.T. helped with the manuscript revising and data analysis.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐	A description of all covariates tested
☒	☐	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☒	☐	For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☒	☐	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	No software was used.
Data analysis	No software was used.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:
- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All data are reported in the paper or the supplementary materials.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☐ Life sciences ☐ Behavioural & social sciences ☒ Ecological, evolutionary & environmental sciences

Ecological, evolutionary & environmental sciences study design

All studies must disclose on these points even when the disclosure is negative.

Study description	Here, we aim to determine whether crop plants wheat and lettuce growing in hydroponic systems and sand matrices or a sandy soil are able to take up PS or PMMA plastic beads (ranging from submicrometer- to micrometer-sized) from nutrient solution and wastewater and translocate these particles from roots to shoots, and if so, to identify the uptake sites and pathways. Plants grown in solution that lacked plastic beads suspension were used as controls. Each treatment was replicated at least three times.
Research sample	Wheat was chosen as a representative of monocot plants because it is one of the main staple foods worldwide; lettuce was selected as a representative of dicot plants because it is a popular leafy vegetable. Seeds of wheat (Triticum aestivum L.,) and lettuce (Lactuca sativa L., Rosa) were provided by academy of agricultural sciences.
Sampling strategy	To identify the uptake mechanism and pathways of microplastic by the plants, for each species, transverse and longitudinal sections of six plants per treatment group were examined by confocal microscopy before representative images were selected. For each species, six plants per treatment group were examined using Scanning Electron Microscopy.
Data collection	The third and sixth author inspected the plant tissue using a confocal laser scanning microscope and collected the images. The fourth and seventh author examined the samples by a scanning electron microscope and collected the image. X-ray computed microtomography (μ-CT) was conducted by the third author using a high-resolution X-ray μ-CT system. The sixth author analyzed the mechanical properties of the PS beads using a Dimension Icon atomic force microscope system and collected the images.
Timing and spatial scale	The study were conducted during the periods from November 2017 to March 2020. The data was collected in the same place in our study.
Data exclusions	No data was excluded from analyses in our study.
Reproducibility	For each experiment, all attempt to repeat the experiment were successful.
Randomization	In the experiment, each specie of plants were allocated into different groups randomly.
Blinding	Blinding was used during the data acquisition and analysis in our study.

Did the study involve field work? ☐ Yes ☒ No

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.
